## Abstract

Applicative functors can be found in different contexts. In functional programming, they abstract the addition of effects to types. But also rather mathematical constructs like sets and infinite containers are examples. The key property of applicative functors is that they lift functions to augmented computations. These can chain effects, for example, or process many values in parallel.

We present a proof method based on applicative lifting, implemented for the Isabelle/HOL proof assistant. Hinze has shown that equations are often preserved when lifted to an applicative functor. While functors are represented naturally in the types of HOL, it is not directly possible to reason based on Hinze's findings. We propose an algorithm which computes a normal form of applicative expressions, together with a checked proof of equivalence. We explain formally how this normal form relates equations and their lifted counterpart. Because not all equations can be handled this way, we apply abstraction algorithms, as known from combinatory logic, to applicative expressions. Depending on the functor, different combinators can be lifted, which increases the flexibility of our proof method. We choose a fixed collection of combinators, which we consider to cover relevant cases. Scope and implementation of each case are discussed. We provide the combined development as a ready-to-use package for Isabelle, and demonstrate its usability on algebraic structures lifted to streams and infinite trees.

# 1 Introduction

## 1.1 Motivation

Interactive theorem provers emphasize the human aspect of mathematical work. Rather than relying on fully automatic proof search, the user guides the process with their own understanding [8]. This requires a sufficiently expressive interface with features beyond plain logical calculus. In particular, there exists a demand for automation and abstraction of patterns [2]. It is thus common to extend proving environments with (sometimes domain-specific) tools.

In this report we present a particular variant of lifting we have implemented for the Isabelle/HOL proof assistant [15]. The term “lifting” is used in different contexts, often informally. It vaguely refers to the transfer of mathematical objects between domains, while preserving a certain relationship. A concrete example are lifts of paths in topology. There is also an existing Isabelle package [13] which lifts definitions to quotient types. Here we consider a slightly different meaning of lifting: The transfer of operations and their properties to generic structures. Since HOL is a typed logic, it is natural to represent these structures as parametric types. Let us look at a simple example.

**Example 1.** For each type  $\alpha$  there is a corresponding type  $\alpha_{set}$  of sets with elements from  $\alpha$ . Addition is a binary operator  $+$  defined on natural numbers, amongst others. How could addition of sets of natural numbers be defined, such that some relation to  $+$  remains? The canonical way to combine two sets into a set of pairs is the cartesian product. Therefore, we define

$$X \oplus Y = \{x + y \mid x \in X, y \in Y\}. \quad (1.1)$$

We interpret  $\oplus$  as the lifting of  $+$  to sets. Note that similar definitions are possible for other operators like multiplication, and other element types such as real numbers. A property of addition is associativity,

$$\forall xyz. (x + y) + z = x + (y + z). \quad (1.2)$$

It can be translated to sets of natural numbers,

$$\forall XYZ. (X \oplus Y) \oplus Z = X \oplus (Y \oplus Z), \quad (1.3)$$

where it holds as well, as one can check with a slightly laborious proof. The two sides of the latter equation can be regarded as functions with three arguments. They are the lifted counterparts of the former equation (1.2). ▲

Hinze [10] came across similar patterns and proceeded to investigate the conditions under which lifted equations are preserved. He noticed that lifting can be defined in an intuitive fashion if the target structure is an applicative functor [14]. These come with two constants, usually denoted *pure* and  $\diamond$  (“ap”), which lift a single object and the notion of function application, respectively. Applicative functors must also satisfy some properties, which we restate in Section 1.4.

Every monad is an applicative functor. Monads are a common mechanism for handling effects in functional programming [21]. Such being the case, they are also useful for modelling and verification. From this context we can borrow quite a few examples of applicative functors: Sum types with one variable type (known as **Either** in Haskell), the reader monad or environment functor, the exception/backtracking list monad [20], the state monad, and parser combinators. Hinze originally worked on streams (infinite lists) and infinite trees [9, 11]. We conclude that there are indeed relevant applicative functors, which supports the argument that this kind of lifting is a useful abstraction.

**Example 1** (continued). Back to sets, we obtain an applicative functor if *pure* is the singleton set constructor  $x \mapsto \{x\}$ ;  $F \diamond X$  takes a set of functions  $F$  and a set of arguments  $X$  with compatible type, applying each function to each argument:

$$F \diamond X = \{fx \mid f \in F, x \in X\}. \quad (1.4)$$

Now we can express lifted addition directly in terms of the base operation:<sup>1</sup>

$$X \oplus Y = \text{pure}(+) \diamond X \diamond Y. \quad (1.5)$$

(The operator  $\diamond$  is left-associative.) This definition is equivalent to the previous one (1.1), but not specific to sets anymore. ▲

As we have seen earlier, lifting can be generalized to equations. One of Hinze’s results is that a fundamental relationship exists between the associative properties (1.2) and (1.3)—the lifted form can be proven for all applicative functors, not just *set*. The proof uses a certain normal form, which separates the lifted operation from the variables. Moreover, this is possible for other equations as well, but not all equations can be lifted to all functors. Stronger conditions are required if the list of quantified variables is different for each side of the equation. (The left-to-right order is relevant, but not the nesting within the terms.) These conditions must basically ensure that the functor does not add “too many effects” which go beyond the simple embedding of a base type. Such effects may be evoked if a variable takes an impure value, i.e., a value which is not equal to *pure* $x$  for any  $x$ . Hinze showed that sufficient conditions can be expressed in terms of combinators as known from combinatory logic.

These findings justify direct proofs of lifted equations. It is desirable to provide these automatically in a proof assistant.

**Example 2.** We try to lift the fact that zero is a left absorbing element for multiplication of natural numbers,  $\forall x :: \text{nat}. 0 \cdot x = 0$ , to sets. Note that the variable  $x$  occurs only on the left. But the lifted equation does not hold: If  $x$ , now generalized to *nat set*, is instantiated with the empty set, then

$$\text{pure}(\cdot) \diamond \text{pure} 0 \diamond \{\} = \{\} \neq \text{pure} 0.$$

Here the effect of  $\{\}$  is that it cancels out everything else if it occurs somewhere in an lifted expression. This makes it impossible to lift any equation to *set* if a variable occurs only on one side. We will see that other functors permit this lifting. ▲

---

<sup>1</sup>As customary in HOL, we treat binary operators as curried functions.

## 1.2 Contributions and Overview

Our primary goal is to provide an Isabelle/HOL proof method which reduces lifted equations to their base form. The method can be instantiated for arbitrary applicative functors. The user is then able to prove the lifted equations directly without having to invent a specific proof strategy, or even simulate the approach taken here. Apart from the theoretical appeal of the method, the resulting proof text is usually more concise due to the higher level of abstraction. Together with some supporting infrastructure, the proof method forms a basic package for reasoning with applicative functors. It targets Isabelle version 2015.

Hinze’s work is the basis for the package. He has identified the suitability of applicative functors and shown necessary conditions for lifting of equations. However, we needed to adapt the details to the HOL environment in order to construct actual proofs. This construction is programmed directly on top of Isabelle’s ML interface. We have therefore derived the correctness and some other properties of our approach formally using a simplified calculus. Moreover, we have further extended the idea of combinators as building blocks for lifting, generalizing Hinze’s model conditions. Consequently, the package supports several combinator sets which functors may exhibit, each capable of lifting different sets of equations. A particular motivation to implement this package are algebraic properties. The HOL theories provide a collection of type classes for structures like monoids, groups, etc. We could simplify a large subset of their proofs when lifted to streams and infinite trees. On the user level, the new proofs are no longer dependent on the particular type.

The remainder of this report is organized as follows: The present section continues with some background information on Isabelle/HOL, applicative functors, and a concrete definition of lifting. Section 2 describes the design considerations, discusses the choice of embedding, and provides a high-level overview of the proof method. In the next two sections, we present the details of the two strategies we have implemented: Section 3 shows an implementation of the normal form of lifted expressions; Section 4 is concerned with combinators and the application of bracket abstraction to applicative terms. Section 5 illustrates how the proof method is applied, and gives examples of what we have proven with it. Finally, we conclude this report in Section 6 with a comparison of related packages and an outlook on possible extensions.

## 1.3 Background: Proving with Isabelle/HOL

Isabelle was originally designed as a framework for interactive theorem proving, without being restricted to a specific logical system [17]. However, one chooses a particular object-logic in order to construct a theory and prove theorems. In this paper, we focus on the Isabelle/HOL object-logic [15]. It implements the higher-order logic which was used in the HOL system, another proving environment [6]. Isabelle/HOL (or HOL from here on) is arguably the most popular object-logic of Isabelle, as it comes with an extensive library of readily formalized mathematics. It also supports modelling of functional programs by means of datatypes and recursive functions, making it suitable for verification tasks.

The basis of HOL is a slightly extended variant of simply-typed lambda calculus. Therefore, every object (and every term representing such an object) has a certain type attached to it. We use lower-case greek letters  $\alpha$ ,  $\beta$ ,  $\gamma$  as meta-variables for types. The language of types consists of base types, type variables, and compound types. Base types are represented by their name and include fundamental types like the booleans *bool* and the natural numbers

*nat*. Type variables stand for arbitrary types. In Isabelle syntax, they are distinguished by a prefixed prime, e.g.  $'a$ ,  $'b$ ,  $'c$ . The polymorphism in HOL is quite restricted, since higher-ranked types cannot be expressed: There is no explicit quantifier on the type level. This rules out functions which take a polymorphic function as an argument and apply it to values of different types. Compound types are built up of a type constructor and a list of types. The type constructor determines the number of argument types. For example, the unary type constructor *set* denotes sets with elements of a certain type. The argument is written on the left as in *nat set*, the type of sets of natural numbers. Multiple types are written in parentheses:  $(\alpha, \beta)fun$ . *fun* is the special type constructor for (total) functions from  $\alpha$  to  $\beta$ . More commonly, the infix operator  $\Rightarrow$  is used. It is right-associative, i.e.  $\alpha \Rightarrow \beta \Rightarrow \gamma$  is notation for  $(\alpha, (\beta, \gamma)fun)fun$ . Note that type constructors are different from types and must always be concrete. In particular, it is not possible to use a variable in place of a type constructor!

Terms follow the standard rules of lambda calculus. Atomic terms are constants and variables. Application of a function  $f$  to an argument  $x$  is written  $fx$ . Functions with multiple arguments are commonly curried in HOL; we can drop parentheses accordingly:  $fx y$  is the same as  $(fx)y$ . Abstraction of a term  $t$  over the variable  $x$  is written  $\lambda x. t$ . Terms must be well-typed, of course. The types of variables and polymorphic constants can usually be omitted, since they are inferred automatically. Explicit type constraints are denoted by  $t :: \alpha$  and may occur anywhere in a term. While all terms are represented internally roughly as shown above, Isabelle comes with extensible notation support.

**Example 3.** We already introduced the type *nat*. Common arithmetic operators are available, like<sup>2</sup>  $plus :: nat \Rightarrow nat \Rightarrow nat$ . We can also write infix operators:

$$\lambda(x :: nat) y. 1 + x * y$$

is a function which multiplies two natural numbers and adds one to the result. Another important type family are sets. They can be specified as finite collections  $\{\}$ ,  $\{a, b, c\}$  etc., and by using set comprehension. Logical formulas are centered around truth values. Thus, the usual connectives like conjunction  $\wedge$  and implication  $\longrightarrow$  operate on type *bool*. Quantifiers work just as expected: The term

$$\forall(x :: nat) y. x + y = y + x$$

states that addition of natural numbers is commutative. Note that  $=$  is just another operator of polymorphic type  $'a \Rightarrow 'a \Rightarrow bool$ . ▲

In order to support different object-logics, Isabelle contains an immediate layer, the meta-logic Pure (see e.g. [22, Chapter 2]). It is an “intuitionistic fragment of higher-order logic” [23, p. 27]. Pure has two main uses within the Isabelle framework: representation and manipulation of both deduction rules and goal states. While our user interface is intended to be used with HOL, the underlying theorems are always represented as propositions of Pure. Therefore it plays an ancillary role in our tool. The following operators are distinct from those of HOL: meta-quantification  $\wedge$  instead of the universal quantifier  $\forall$ , and meta-equality  $\equiv$  instead of  $=$ . Each of these are logically equivalent, though. In particular, the generic rewriting and simplification tools work with  $\equiv$ . As an example of Pure, consider the symmetry axiom for  $\equiv$  in traditional rule format,

$$\frac{\Gamma \vdash x \equiv y}{\Gamma \vdash y \equiv x}.$$

<sup>2</sup>These functions actually have a more generic type (they are overloaded).

Deduction in Isabelle handles the context  $\Gamma$  automatically, and therefore does not have to be stated in the corresponding proposition. The dependency of the conclusion on the hypothesis translates to meta-implication; the outermost meta-quantified variables (and all type variables) are turned into schematic variables, which are free variables distinguished by the prefix  $?$ . Thus, the symmetry axiom appears as the theorem

$$\text{symmetric} : \quad ?x \equiv ?y \implies ?y \equiv ?x.$$

Schematic (type) variables are eligible for instantiation by some core functions.

Isabelle is an LCF-style prover, i.e., proofs are composed by invoking trusted, primitive inferences programmed in the implementation language SML, at least on the lowest level. For instance, the symmetry axiom is available in combination with modus ponens as the function `Thm.symmetric`, which takes a theorem  $x \equiv y$  and returns a new theorem  $y \equiv x$ . The function is part of the large SML interface of Isabelle, which not only constitutes its implementation, but can also be used for new tools.

In contemporary use of Isabelle, user input to the system is expressed in the Isar language [24, 25, 23]. It aims to encode proofs in a way that is formal, i.e. has precise semantics, but still resembles informal patterns of reasoning. The basic organization unit in Isar is a theory. The body of a theory consists of a sequence of commands, which consecutively augment the logical context by declarations of various kinds. Other theories may be imported in the beginning, leading to a acyclic graph of theory dependencies. The set of data stored within a theory can be extended through the programming interface. This is relevant to us, because it allows us to register applicative functors in the theory context.

Commands constitute the so-called outer syntax of Isar. Types and terms that occur within them are parsed separately, according to the inner syntax. In certain cases, a command may put the theory state into proof mode. After the proof is finished, the associated goal becomes a fact, which is further handled by some associated code. The important **lemma** family of commands works this way, for example. New commands are frequently introduced for specification purposes. For example, algebraic datatypes can be defined with the **datatype** command. Finally, the following two extensible syntactical categories are commonly used in Isar: Proof methods denote (possibly parameterized) operations on the goal state within a regular Isar proof. These operations are provided by code and thus can be arbitrarily complex. Attributes invoke further processing steps on already proven facts, either transforming them or causing additional declarations to the context.

## 1.4 Background: Applicative Functors and Lifting

Applicative functors were introduced by McBride and Paterson [14] in order to abstract a recurring theme they observed in the programming language Haskell. In fact, their findings already included some examples of lifting. They defined an applicative functor as a unary type constructor  $f$  with associated constants

$$\begin{aligned} \text{pure}_f &:: \alpha \Rightarrow \alpha f, \\ (\diamond_f) &:: (\alpha \Rightarrow \beta) f \Rightarrow \alpha f \Rightarrow \beta f. \end{aligned}$$

We omit the subscripts if the functor is clear from the context. Moreover, the following laws must be satisfied:

$$\begin{aligned}
\text{pure } id \diamond u &= u && \text{(identity)} \\
\text{pure } (\cdot) \diamond u \diamond v \diamond w &= u \diamond (v \diamond w) && \text{(composition)} \\
\text{pure } f \diamond \text{pure } x &= \text{pure } (fx) && \text{(homomorphism)} \\
u \diamond \text{pure } x &= \text{pure } (\lambda f. fx) \diamond u && \text{(interchange)}
\end{aligned}$$

We have already seen how the two constants can be used to build terms. McBride and Paterson coined the term “idiom” to refer to a particular interpretation of such terms. In line with Hinze, we will use “applicative functor” and “idiom” interchangeably. Also note the difference between  $\diamond_f$  and the bind operation of a monad  $m$ . Both take an enhanced function  $((\alpha \Rightarrow \beta)f$  versus  $\alpha \Rightarrow \beta m$ ), but with bind, the result of the function affects the monadic level. A function lifted by an applicative functor is oblivious of its augmented context. In particular, its result cannot influence the overall structure of the computation.

The identity type constructor defined by  $\alpha id = \alpha$  is a trivial applicative functor for  $\text{pure } x = x$ ,  $f \diamond x = fx$ . We can take any abstraction-free term  $t$  and replace each constant  $c$  by  $\text{pure } c$ , and each instance of function application  $fx$  by  $f \diamond x$ . The rewritten term is equivalent to  $t$  when interpreted in the identity idiom. By choosing a different idiom, we obtain a different interpretation of the same term structure. In fact, this is exactly how we define the lifting of  $t$ . However, the terms we are interested in can also contain variables: Equations such as (1.2) are universally quantified. For the purpose of lifting, we ignore quantifiers and treat their variables as free. Like in Example 1, the variables of lifted equations should range over the lifted type. Note that these can take impure values. A term consisting only of  $\text{pure}$  and  $\diamond$  applications and free variables is then called an *idiomatic expression*.

Every idiom is a functor, of course, and thus has a mapping function. One obtains an equivalent formalization of idioms:

$$\begin{aligned}
\text{map}_f &:: (\alpha \Rightarrow \beta) \Rightarrow \alpha f \Rightarrow \beta f, & \text{map}_f gx &= \text{pure } g \diamond x, \\
\text{unit}_f &:: ()f, & \text{unit}_f &= \text{pure } (), \\
(\star_f) &:: \alpha f \Rightarrow \beta f \Rightarrow (\alpha, \beta)f, & x \star_f y &= \text{pure } (\lambda xy. (x, y)) \diamond x \diamond y.
\end{aligned}$$

Some of Hinze’s proofs make use of these definitions. Dealing with product types can be a bit cumbersome in HOL, though. The curried interface therefore seems to be a better choice, and we will focus solely on that.

## 2 Requirements and Basic Design

### 2.1 Requirements

The following is the minimal set of user actions our Isabelle package shall support:

- a) Declare applicative functors to the theory context. Given a type constructor  $f$ , the functions  $\text{pure}_f$  and  $\diamond_f$ , and proofs for the relevant functor laws, the functor is registered with the package such that it can be used in subsequent invocations of the proof method.
- b) Prove lifted equations  $a'[\vec{x}] = b'[\vec{x}]$ , where  $a'$  and  $b'$  are idiomatic expressions with free variables  $\vec{x}$ , using the base equation  $\forall \vec{y}. a[\vec{y}] = b[\vec{y}]$ . More precisely, if there is a subgoal stating the former, applying the proof methods transforms the goal state to the latter. The functor should either be detected automatically, or be specified by the user.

The first requirement ensures that our package is reusable, while the second is the core functionality. However, usability is also a concern: In the realm of interactive theorem proving, it is not sufficient to just verify formal objects—we are not extending the logic, after all, but providing a shortcut following a certain principle. We must balance the clarity of the resulting proof document and the amount of work that the user has to put into developing a proof. The following features are possible extensions which may help in this regard:

- c) Declare lifted constants and other terms to the theory context. Generally speaking, if a term  $t$  with free variables  $v_i$  can be expressed as  $\text{pure } t' \diamond v_1 \diamond \dots \diamond v_n$  for some  $t'$ , then the corresponding equation can be registered. The proof methods rewrite with these equations at the beginning, such that the base equation will refer to  $t'$ . This way, the user does not have to transform everything into idiomatic format first.
- d) More flexibility regarding the logical structure of the input proposition. This includes bound variables (quantified by  $\forall$  or  $\wedge$ ), complex subgoals with premises, and cases where the variables of the lifted equation have been substituted by some terms.
- e) Related proof methods and attributes, for example for forward lifting of facts stating a base equation.
- f) Inspection and tracing output. This is particular useful if something does not work as expected.
- g) Extend the notion of lifting beyond equations. It is possible to define lifting for other logical operators. For example, the cancellation law  $a + b = a + c \longrightarrow b = c$  consists of two equations, joined by implication. We can interpret it in different domains, e.g., for integers and for streams of integers with element-wise addition. In this example, the law is true for both interpretations. We are not able to handle such propositions with a method just for equations.

The current version at the time writing supports c) and d), as well as the forward lifting described in e). In the remainder of this section, we will explain the design decisions we have made in order to fulfill the requirements. Furthermore, the registration infrastructure and the basic proof approach are explained.

## 2.2 Choice of Embedding

The basic principle of proof composition in Isabelle is resolution with a proven theorem, using it as a rule of inference. Here we argue that it is not possible to prove lifting as a single theorem, and then we discuss potential remedies. We are interested in applicative functors on the type level, where application is based on the standard function space. Therefore, each idiom comes with a type family which is indexed by a distinguished type variable, and the related functions and laws are polymorphic in this index. This is the natural form of idioms in the HOL libraries; all examples mentioned in Section 1.1 are parametric datatypes. The proof method should work directly with equations involving these. Regardless of the mechanism of proof construction, it needs a type constructor as a parameter. This concept is foreign to the type system of Pure and HOL—we already referred to the fact that type constructors are fixed. Another issue is the lack of polymorphism in the inner logic: We cannot have, say, a schematic variable *?pure* and use it with different types within the same proposition or proof.

One solution is to define a custom logic, including a term language, axioms and meta theorems, and formalize it using the available specification tools. In our case, the language is that of idiomatic expressions,<sup>3</sup> the axioms describe an equality judgment which is compatible with the applicative functor laws, and lifting of equations is a theorem. This is a *deep embedding* of the logic [26]. With its tools for algebraic datatypes and recursive functions, reasoning about such an embedding is quite manageable in HOL. However, we want to prove propositions involving objects of HOL itself, not just their encodings in the embedded language. Some machinery, known as reflection, needs to perform the encoding and transfer back results. It must be implemented necessarily outside of the logic, but can be generic. Chaieb and Nipkow have implemented a proof procedure using a deep embedding and reflection in Isabelle [4]. They point out that their approach also functions as a verification of the proof procedure, is portable and has smaller proofs than those obtained by automating inference rules. Their reflection system does not support polymorphism to the extent we need, though.

The package for nonfree datatypes [19] is deeply embedded as well. Its constructions must work with arbitrary types. In the underlying framework, Schropp [18] proposed the use of a “pseudo-universe”, a sum type combining all relevant types. The meta-theory of the package carries a type parameter which is instantiated with a suitable pseudo-universe for every construction. It may be possible to use the same approach for idiomatic expressions, since the number of types occurring in an idiomatic expression is finite. This number can be linear in the size of the expression, though, which bloats the intermediate terms during reflection. A bigger problem is the axiomatization of idioms. For instance, the identity law would refer to a function of type  $\alpha \Rightarrow \alpha$  for each type  $\alpha$  in the pseudo-universe. Thus, the universe needs to be closed under function types. It is not clear to the author how this could be modelled.

---

<sup>3</sup>Base equations can be interpreted as expressions in the identity idiom.

A different approach, which is the one we will take, is a *shallow embedding*. The formulas (here, idiomatic terms) are expressed directly in the language of HOL. Due to aforementioned restrictions, meta-theoretical results must be provided in specialized form for each case. We use the powerful ML interface of Isabelle to program the proof construction, composing inferences according to the structure of the input equation. The handling of polymorphism is simplified, as we have full control over term and theorem instantiations. The system still verifies the soundness of the synthesized proofs. On the other hand, one has to assert externally that the construction algorithm itself is correct, i.e., complete. The main part of this report therefore justifies these algorithms.

## 2.3 Proof Strategy

The ML code of the package can be considered in two parts. One is concerned with registration of idioms and access to the recorded information, the other provides the actual proof methods. We start with a summary of the former component. It does not only store the idioms declared with the **applicative** command (see Section 5.1), but also deals with the high degree of polymorphism. First, we need to represent the concept of an idiom. Instead of a plain type constructor we use type schemes  $f[a]$ , which are normal HOL types with (in this case) one distinguished type variable  $a$ . This variable has to be tracked externally in ML because of the lack of type quantifiers in the type system. The lifted type of  $\alpha$  is then obtained by substitution of  $a$  by  $\alpha$  in  $f[a]$ . The functions  $\text{pure}_f$  and  $\diamond_f$  thus have types  $a \Rightarrow f[a]$  and  $f[a \Rightarrow b] \Rightarrow f[a] \Rightarrow f[b]$ , respectively. We allow additional type variables in functor signatures, which therefore represent families of functors. These variables are always instantiated with the same types throughout a proof. This is useful for idioms based on sum types  $\alpha + \beta$ , for instance. As a further refinement, all type variables may be constrained by a sort. Sorts in Pure are type classes [22]. The sort of the distinguished variable in  $f$  must be compatible with the function type constructor.

These logical entities together form the signature of the idiom  $f$ . We define functions which compose and destruct types and terms related to  $f$ . One problem is to identify terms of the form  $\text{pure } \_$  and  $\_ \diamond \_$  in the first place. We do not want to restrict the term structure of the functor “constants”, since some useful predefined concepts in the HOL libraries are abbreviations of compound terms. Isabelle’s higher-order matching appears to be a proper solution in practice, using  $\text{pure } v$  (or  $v_1 \diamond v_2$ ) with new variables  $v$  ( $v_1, v_2$ ) as the pattern.

The remaining code uses these functions to provide several layers of conversions and tactics. A wrapper tactic prepares the subgoal to solve. This includes dealing with universal quantifiers and local premises. Then, we rewrite the subgoal using the declared rules for lifted constants. Only those related to  $f$  are used, the reason being that overeager, unwanted unfolding may be difficult to reverse. The result of this preparation is a subgoal which is a simple equation of two idiomatic expressions. We provide two variants of the basic lifting step. They have in common that both expressions are transformed into *canonical form*:

$$\text{pure } g \diamond s_1 \diamond \dots \diamond s_m = \text{pure } h \diamond t_1 \diamond \dots \diamond t_n,$$

We apply appropriate congruence rules until the subgoal is reduced to  $g = h$ . If either  $m \neq n$  or  $s_i \neq t_i$  for some  $i$  (as terms modulo  $\alpha\beta\eta$ -conversion), the proof method fails. Since  $g$  and  $h$  are at least  $n$ -ary functions, we can further apply extensionality, and obtain the subgoal

$$\bigwedge x_1 \dots x_n. g x_1 \dots x_n = h x_1 \dots x_n.$$

This is the transformed proof state presented to the user.

Hinze’s Normal Form Lemma [10, p. 7] asserts the existence of a normal form for idiomatic expressions where each variable occurs only once. As it turns out, we can compute it for arbitrary expressions. This normal form is a canonical form. Therefore, the first variant simply replaces both sides of the equation with the normal form. The details of the normalization algorithm are described in Section 3. There we will also show that the transformed equation is indeed the base form of the original equation. The other implementation is a superset of the normal form approach. Instead of using the unique normal form, we construct canonical forms explicitly such that the condition  $\vec{s} = \vec{t}$  is satisfied. The idiom under consideration limits the set of equivalent canonical forms, though. The construction is related to bracket abstraction of lambda terms—we add combinators to the term in order to separate the lifted part from the variables. This is further explained in Section 4.

### 3 Normal Form Conversion

McBride and Paterson [14] noted that idiomatic expressions can be transformed into an application of a pure function to a sequence of impure arguments. They called this the *canonical form* of the expression. Hinze [10, Section 3.3] gave an explicit construction based on the monoidal variant of applicative functors. Transforming the terms in this way is useful for our purpose, because the arguments of the remaining *pure* terms reflect the equation that was lifted. The soundness of the algorithm depends only on the applicative laws, making it the most general approach regarding functors (but not regarding lifted equalities). We will later show that all transformations based on the applicative laws yield a unique canonical form, modulo  $\alpha\beta\eta$ -conversion. Therefore, we follow Hinze and refer to this particular canonical form as the *normal form*. The distinction is necessary, as we will consider other canonical forms in Section 4, which are justified by additional laws.

In the following, we define lifting and normalization formally, based on a syntactic representation of idiomatic terms. While this presentation is more abstract than what is actually happening in Isabelle, it makes it easier to demonstrate correctness and some other properties. Unlike Hinze, we use the *pure*/ $\diamond$  formalism. Then we describe the implementation of the normalization procedure in Isabelle/ML.

#### 3.1 The Idiomatic Calculus

In Section 1.4, we introduced idiomatic expressions built from *pure* and  $\diamond$  constants of an applicative functor. This structure maps straightforward to a recursive datatype, given that there is a representation for arguments of *pure*. These must have some structure as well, such that the applicative laws can be expressed. It should also be possible to have “opaque” idiomatic subterms, which cannot (or should not) be written as a combination of *pure* and  $\diamond$ . This is primarily useful for variables ranging over lifted types, but more complex terms can occur too. Therefore it makes sense to refer to general lambda terms in both cases; then we can define semantics consistently. Types are ignored here for simplicity. However, all results are compatible with the restrictions of simply typed lambda calculus.

**Definition 1** (Untyped lambda terms). Let  $\mathcal{V}$  be an infinite set of variable symbols. We assume that  $f, g, x, y$  are disjoint variables in the following formulas. The set of untyped lambda terms is defined as

$$\mathcal{T} ::= \mathcal{V} \mid (\mathcal{T} \mathcal{T}) \mid \lambda \mathcal{V}. \mathcal{T} \quad (3.1)$$

An equivalence relation on  $\mathcal{T}$  is a  $\mathcal{T}$ -congruence iff it is closed under application and abstraction. Let  $=_{\alpha\beta\eta}$  be the smallest  $\mathcal{T}$ -congruence containing  $\alpha$ -,  $\beta$ -, and  $\eta$ -conversion.  $\blacktriangle$

**Definition 2** (Idiomatic terms). The set of idiomatic terms is defined as

$$\mathcal{I} ::= \text{term } \mathcal{T} \mid \text{pure } \mathcal{T} \mid \mathcal{I} \text{ 'ap' } \mathcal{I}. \quad (3.2)$$

By convention, the binary operator ‘ap’ associates to the left. An  $\mathcal{I}$ -congruence is an equivalence relation closed under ‘ap’. We overload notation and reuse  $=_{\alpha\beta\eta}$  for idiomatic terms,

Figure 3.1: (pure  $a$  ‘ap’  $b$ ) ‘ap’ term  $c$  as a tree.

Figure 3.2: A term in canonical form.

where it stands for structural equality modulo substitution of  $=_{\alpha\beta\eta}$ -equivalent lambda terms. The  $\mathcal{I}$ -congruence  $\simeq$  is induced by the rules

$$x \simeq \text{pure}(\lambda x. x) \text{ ‘ap’ } x \quad (3.3)$$

$$g \text{ ‘ap’ } (f \text{ ‘ap’ } x) \simeq \text{pure } \mathbf{B} \text{ ‘ap’ } g \text{ ‘ap’ } f \text{ ‘ap’ } x \quad (3.4)$$

$$\text{pure } f \text{ ‘ap’ } \text{pure } x \simeq \text{pure}(fx) \quad (3.5)$$

$$f \text{ ‘ap’ } \text{pure } x \simeq \text{pure}((\lambda x. \lambda f. fx)x) \text{ ‘ap’ } f \quad (3.6)$$

$$s =_{\alpha\beta\eta} t \implies s \simeq t \quad (3.7)$$

where  $\mathbf{B}$  abbreviates  $\mathbf{B} \equiv \lambda g. \lambda f. \lambda x. g(fx)$ . ▲

term represents arbitrary values in the lifted domain, whereas pure lifts a value. The introduction rules for the relation  $\simeq$  are obviously the syntactical counterparts of the applicative laws. Together with symmetry, substitution, etc., they give rise to a simple calculus of equivalence judgements. The intuitive meaning of  $s \simeq t$  is that the terms can be used interchangeably. For example, there is a derivation for

$$\text{pure } g \text{ ‘ap’ } (f \text{ ‘ap’ } x) \simeq \text{pure}(\mathbf{B} g) \text{ ‘ap’ } f \text{ ‘ap’ } x \quad (3.8)$$

from (3.4), where  $g$  is instantiated with  $\text{pure } g$ , and a substitution along (3.5) on the right-hand side.

Idiomatic terms are visualized naturally as trees. This will be helpful in explaining term transformations. Figure 3.1 shows the conventions: Inner nodes correspond to ‘ap’, leaves are either pure terms (boxes) or opaque terms (circles). Whole subterms may be abbreviated by a triangle. A term has canonical form if it consists of a single pure node to which a number of opaque terms (or none) are applied in sequence. Figure 3.2 gives a general example. A formal construction follows:

**Definition 3** (Canonical form). The set  $\mathcal{C} \subset \mathcal{I}$  of idiomatic terms in canonical form is defined inductively as

$$\text{pure } x \in \mathcal{C}, \quad (3.9)$$

$$t \in \mathcal{C} \implies t \text{ ‘ap’ } \text{term } s \in \mathcal{C}. \quad (3.10)$$

▲

It is not entirely obvious how a canonical form can be derived from equations (3.3)–(3.6). Rewriting blindly with these is prone to infinite recursion. Therefore we need a more controlled algorithm. As we have said before, we use *normal form* to refer to the particular canonical form derived from those equations. Consider an idiomatic term  $t$ . If  $t$  is a single

Figure 3.3: The “pure-rotate” step.

pure term, it is already in normal form. The case  $t = \text{term } x$  is also easy: Due to (3.3), we have  $t \simeq \text{pure}(\lambda x. x) \text{ 'ap' } t$ , which is in normal form. But in the case of  $t = u \text{ 'ap' } v$ , various steps could be performed, depending on the subterms. We simplify the situation by normalizing each subterm recursively, so we get an equivalent term  $u' \text{ 'ap' } v'$  where  $u', v' \in \mathcal{C}$ .

Now let us assume that  $u'$  is just  $\text{pure } g$ . If  $v'$  is also a pure term, they can be combined along (3.5). Otherwise, the term looks like the one on the left of Figure 3.3. As is shown there, the term tree can be rotated such that one opaque term moves to the outer-most level. This is the same equivalence as stated in (3.8). Because the remaining part again has the shape “pure term applied to normal form”, we proceed recursively. In pattern-matching style, the transformation ‘pure-nf’ reads

$$\text{pure-nf}(\text{pure } g \text{ 'ap' } (f \text{ 'ap' } x)) = \text{pure-nf}(\text{pure}(\mathbf{B}g) \text{ 'ap' } f) \text{ 'ap' } x \quad (3.11)$$

$$\text{pure-nf}(\text{pure } f \text{ 'ap' } \text{pure } x) = \text{pure}(fx) \quad (3.12)$$

**Lemma 1.** *For all  $g \in \mathcal{T}$  and  $t \in \mathcal{C}$ ,  $\text{pure-nf}(\text{pure } g \text{ 'ap' } t)$  is well-defined, and<sup>4</sup>  $\text{pure-nf}(\text{pure } g \text{ 'ap' } t) \in \mathcal{C} \simeq \text{pure } g \text{ 'ap' } t$ .*

*Proof.* We prove all claims simultaneously by induction on  $t \in \mathcal{C}$ , where  $g$  is arbitrary.

*Case 1.* Assume  $t = \text{pure } x$  for some  $x \in \mathcal{T}$ . Only the second equation applies, so we have

$$\text{pure-nf}(\text{pure } g \text{ 'ap' } t) = \text{pure}(gx).$$

All pure terms are in  $\mathcal{C}$ , and equivalence follows from (3.5).

*Case 2.* Assume  $t = t' \text{ 'ap' } \text{term } x$  for some  $t' \in \mathcal{C}$ ,  $x \in \mathcal{T}$ , and that the hypothesis holds for  $t'$  and all  $g$ . Only the first equation applies, so

$$\text{pure-nf}(\text{pure } g \text{ 'ap' } t) = \text{pure-nf}(\text{pure}(\mathbf{B}g) \text{ 'ap' } t') \text{ 'ap' } \text{term } x.$$

Instantiating the induction hypothesis, we find that

$$\text{pure-nf}(\text{pure}(\mathbf{B}g) \text{ 'ap' } t') \in \mathcal{C} \simeq \text{pure}(\mathbf{B}g) \text{ 'ap' } t'$$

is well-defined.  $\mathcal{C}$  is closed under application to opaque terms (3.10), hence  $\text{pure-nf}(\text{pure } g \text{ 'ap' } t) \in \mathcal{C}$ . Finally, we have

$$\begin{aligned} \text{pure-nf}(\text{pure } g \text{ 'ap' } t) &\simeq \text{pure}(\mathbf{B}g) \text{ 'ap' } t' \text{ 'ap' } \text{term } x \\ &\stackrel{(3.8)}{\simeq} \text{pure } g \text{ 'ap' } (\text{pure } t' \text{ 'ap' } \text{term } x) = \text{pure } g \text{ 'ap' } t. \end{aligned} \quad \square$$

<sup>4</sup> $a \in S \simeq b$  abbreviates “ $a \in S$  and  $a \simeq b$ ”.

Figure 3.4: The “rotate” step.

Going back to  $u' \text{ 'ap' } v'$ , we assumed that  $u'$  is a pure term. The case where  $v'$  is pure instead can be translated to the former by

$$\text{nf-pure}(f \text{ 'ap' } \text{pure } x) = \text{pure-nf}(\text{pure}((\lambda x. \lambda f. fx)x) \text{ 'ap' } f) \quad (3.13)$$

**Lemma 2.** *For all  $t \in \mathcal{C}$  and  $x \in \mathcal{T}$ ,  $\text{nf-pure}(t \text{ 'ap' } \text{pure } x)$  is well-defined, and  $\text{nf-pure}(t \text{ 'ap' } \text{pure } x) \in \mathcal{C} \simeq t \text{ 'ap' } \text{pure } x$ .*

*Proof.* Follows from Lemma 1 and (3.6). □

Finally, we look at general  $u', v'$ . A term rotation is useful again, see Figure 3.4. Before recursion, we must normalize the subterm  $\text{pure } \mathbf{B} \text{ 'ap' } s$ . But we already know how to do this: by ‘pure-nf’. The base case is reached when  $v'$  is a single pure term, which is the domain of ‘nf-pure’. The corresponding transformation is therefore

$$\text{nf-nf}(g \text{ 'ap' } (f \text{ 'ap' } x)) = \text{nf-nf}(\text{pure-nf}(\text{pure } \mathbf{B} \text{ 'ap' } g) \text{ 'ap' } f) \text{ 'ap' } x \quad (3.14)$$

$$\text{nf-nf}(t) = \text{nf-pure}(t) \quad (\text{otherwise}) \quad (3.15)$$

**Lemma 3.** *For all  $s, t \in \mathcal{C}$ ,  $\text{nf-nf}(s \text{ 'ap' } t)$  is well-defined, and  $\text{nf-nf}(s \text{ 'ap' } t) \in \mathcal{C} \simeq s \text{ 'ap' } t$ .*

*Proof.* The proof is similar to the one of Lemma 1, by induction on  $t \in \mathcal{C}$  and arbitrary  $s \in \mathcal{C}$ .

*Case 1.* Assume  $t = \text{pure } x$  for some  $x \in \mathcal{T}$ . The second equation applies, so we have

$$\text{nf-nf}(s \text{ 'ap' } t) = \text{nf-pure}(s \text{ 'ap' } \text{pure } x).$$

Since  $s \in \mathcal{C}$ , the claim follows directly from Lemma 2.

*Case 2.* Assume  $t = t' \text{ 'ap' } \text{term } x$  for some  $t' \in \mathcal{C}$ ,  $x \in \mathcal{T}$ , and that the hypothesis holds for  $t'$  and all  $s \in \mathcal{C}$ . Only the first equation applies,

$$\text{nf-nf}(s \text{ 'ap' } t) = \text{nf-nf}(\text{pure-nf}(\text{pure } \mathbf{B} \text{ 'ap' } s) \text{ 'ap' } t') \text{ 'ap' } \text{term } x.$$

We have  $\text{pure-nf}(\text{pure } \mathbf{B} \text{ 'ap' } s) \in \mathcal{C} \simeq \text{pure } \mathbf{B} \text{ 'ap' } s$  from Lemma 1. Thus we can instantiate the induction hypothesis, and the transformed term is indeed in normal form. Furthermore,

$$\begin{aligned} \text{nf-nf}(s \text{ 'ap' } t) &\stackrel{(\text{IH})}{\simeq} \text{pure-nf}(\text{pure } \mathbf{B} \text{ 'ap' } s) \text{ 'ap' } t' \text{ 'ap' } \text{term } x \\ &\simeq \text{pure } \mathbf{B} \text{ 'ap' } s \text{ 'ap' } t' \text{ 'ap' } \text{term } x \\ &\stackrel{(3.4)}{\simeq} s \text{ 'ap' } (t' \text{ 'ap' } \text{term } x) = s \text{ 'ap' } t. \end{aligned} \quad \square$$

---

**Algorithm 1** Normalization of idiomatic terms.

---

$$\begin{aligned}
\text{normalize}(\text{pure } x) &= \text{pure } x \\
\text{normalize}(\text{term } x) &= \text{pure } (\lambda x. x) \text{ 'ap' } \text{term } x \\
\text{normalize}(x \text{ 'ap' } y) &= \text{nf-nf}(\text{normalize } x \text{ 'ap' } \text{normalize } y) \\
\\
\text{nf-nf}(g \text{ 'ap' } (f \text{ 'ap' } x)) &= \text{nf-nf}(\text{pure-nf}(\text{pure } \mathbf{B} \text{ 'ap' } g) \text{ 'ap' } f) \text{ 'ap' } x \\
\text{nf-nf}(t) &= \text{nf-pure}(t) \quad (\text{otherwise}) \\
\\
\text{pure-nf}(\text{pure } g \text{ 'ap' } (f \text{ 'ap' } x)) &= \text{pure-nf}(\text{pure } (\mathbf{B}g) \text{ 'ap' } f) \text{ 'ap' } x \\
\text{pure-nf}(\text{pure } f \text{ 'ap' } \text{pure } x) &= \text{pure } (fx) \\
\\
\text{nf-pure}(f \text{ 'ap' } \text{pure } x) &= \text{pure-nf}(\text{pure } ((\lambda x. \lambda f. fx) x) \text{ 'ap' } f)
\end{aligned}$$

---

Algorithm 1 summarizes all pieces of the normal form transformation. ‘normalize’ is the entry point and performs the main recursion mentioned in the beginning. We haven’t proved the desired property for ‘normalize’ yet, but this is just a straightforward induction.

**Lemma 4.** *For all  $t \in \mathcal{I}$ ,  $\text{normalize } t$  is well-defined, and  $\text{normalize } t \in \mathcal{C} \simeq t$ .*

*Proof.* By induction on  $t$ , Lemma 3, and equation (3.3). □

At this point, we know that it is always possible to obtain a certain canonical form. This is not sufficient to setup the complete proving process, though. We need to learn a bit more about the structure of idiomatic terms and how the normal form relates to lifting.

**Definition 4** (Opaque subterms). The sequence of opaque subterms of an idiomatic term is defined by the recursive function

$$\text{opaq}(\text{pure } x) = [], \quad \text{opaq}(\text{term } x) = [x], \quad \text{opaq}(s \text{ 'ap' } t) = \text{opaq } s @ \text{opaq } t.$$

@ denotes concatenation of lists. ▲

**Definition 5** (Unlifting). Let  $t$  be some idiomatic term, and  $n = |\text{opaq } t|$ . Let  $v_{i \in \{1..n\}}$  be new variable symbols that do not occur anywhere in  $t$ . The “unlifted” lambda term corresponding to  $t$  is defined as

$$\downarrow t = \lambda v_1. \dots \lambda v_n. \text{vary}_1 t,$$

where

$$\text{vary}_i(\text{pure } x) = x, \tag{3.16}$$

$$\text{vary}_i(\text{term } x) = v_i, \tag{3.17}$$

$$\text{vary}_i(s \text{ 'ap' } t) = (\text{vary}_i s) (\text{vary}_{i+|\text{opaq } s|} t). \tag{3.18}$$

▲

**Example 4.** The definition of  $\downarrow$  may need some explanation. Consider the idiomatic term

$$t \equiv \text{pure } f \text{ 'ap' } x \text{ 'ap' } (\text{pure } g \text{ 'ap' } y \text{ 'ap' } z).$$

The unlifted term is

$$\downarrow t = \lambda a. \lambda b. \lambda c. f a (g b c).$$

The applicative structure is the same, but all opaque terms have been substituted by new bound variables, which are assigned from left to right. We do not define lifting formally here, but it should be clear that this is some sort of inverse operation, given that variables appear only once.  $\blacktriangle$

The interesting properties about these two concepts is that they are preserved by the equivalence relation  $\simeq$ , and can be read directly from the canonical form. Furthermore, we leverage them to show the uniqueness of the normal form.

**Lemma 5.** *For equivalent terms  $s \simeq t$ , the sequences of opaque terms are equivalent w.r.t.  $=_{\alpha\beta\eta}$ , and  $\downarrow s =_{\alpha\beta\eta} \downarrow t$ .*

*Proof.* (Sketch.) By induction on the relation  $s \simeq t$ , where we show  $\text{vary}_i s =_{\alpha\beta\eta} \text{vary}_i t$  instead of  $\downarrow s =_{\alpha\beta\eta} \downarrow t$ . The index  $i$  is arbitrary. The part regarding opaque terms is shown easily for each case: We note that in (3.3)–(3.6), the opaque terms are identical for both sides. By the induction hypothesis, this is also true for the necessary closure rules for symmetry, transitivity, and substitution. It is obvious that (3.7) also preserves opaque terms. Regarding unlifted terms, we have

Case 1. (3.3)

$$\text{vary}_i(\text{pure } (\lambda x. x) \text{ 'ap' } x) = (\lambda x. x) (\text{vary}_i x) =_{\alpha\beta\eta} \text{vary}_i x.$$

Case 2. (3.4) Let  $j = i + |\text{opaq } g|$  and  $k = j + |\text{opaq } f|$ .

$$\begin{aligned} \text{vary}_i(\text{pure } \mathbf{B} \text{ 'ap' } g \text{ 'ap' } f \text{ 'ap' } x) &= \mathbf{B} (\text{vary}_i g) (\text{vary}_j f) (\text{vary}_k x) \\ &=_{\alpha\beta\eta} (\text{vary}_i g) ((\text{vary}_j f) (\text{vary}_k x)) \\ &= \text{vary}_i(g \text{ 'ap' } (f \text{ 'ap' } x)). \end{aligned}$$

Case 3. (3.5) and (3.6) are similar.

Case 4. (3.7) By induction.

Case 5. Symmetry, transitivity, and substitution: These follow from the induction hypothesis and the corresponding properties of  $=_{\alpha\beta\eta}$ .

□

**Lemma 6.** *Let  $\text{pure } f$  be the single pure term in  $t \in \mathcal{C}$ . Then  $f =_{\alpha\beta\eta} \downarrow t$ .*

*Proof.* By induction on  $\mathcal{C}$ . The base case is trivial. For the step case, we need to prove that

$$f' =_{\alpha\beta\eta} \downarrow (g \text{ 'ap' } \text{term } x) = \lambda v_1. \dots \lambda v_n. \lambda v_{n+1}. (\text{vary}_1 g) v_{n+1},$$

where  $\text{pure } f'$  is the single pure term in  $g$ ,  $n = |\text{opaq } g|$ , and  $v_i$  are new variables. The right-hand side can be eta-reduced to

$$\lambda v_1. \dots \lambda v_n. (\text{vary}_1 g) = \downarrow g.$$

From the induction hypothesis we get  $f' =_{\alpha\beta\eta} \downarrow g$ , which concludes the proof. □

This lemma is why we need eta-equivalence and not just use  $=_{\alpha\beta}$ . In fact, we can find a counterexample of equivalent canonical forms that do not agree in the pure function if  $\rightarrow_\eta$  is not available:

$$\text{pure}(\lambda x. x) \text{'ap'} (\text{pure } f \text{'ap'} x) \simeq \text{pure } f \text{'ap'} x \simeq \text{pure}(\lambda x. f x) \text{'ap'} x.$$

The middle term is derived from (3.3), the latter from (3.4).

**Corollary 1.** *The normal form is structurally unique. Formally, if  $s, t \in \mathcal{C}$  and  $s \simeq t$ , then  $s =_{\alpha\beta\eta} t$ .*

Now we have all tools ready to complete the picture. The following theorem shows that (limited) lifting is possible with just the applicative laws. Its proof hints towards the implementation in Isabelle, which is of course based on the normal form: Under the condition that the opaque terms are equivalent, normalizing two idiomatic terms reduces the problem to the “unlifted” terms.

**Theorem 1.** *Let  $s, t \in \mathcal{I}$  with  $\text{opaqs} =_{\alpha\beta\eta} \text{opaqt}$ . If  $\downarrow s =_{\alpha\beta\eta} \downarrow t$  (the base equation), then  $s \simeq t$ .*

*Proof.* From Lemma 4 we obtain normal forms  $s' \simeq s$  and  $t' \simeq t$ . With the base equation and Lemma 5 we get  $\downarrow s' =_{\alpha\beta\eta} \downarrow t'$ . By Lemma 6 and the condition on the opaque subterms, it follows that  $s' =_{\alpha\beta\eta} t'$  and further  $s \simeq t$ .  $\square$

## 3.2 Implementation

We introduced an algorithm for computing the normal form of an idiomatic term, and argued for its central role in lifting. In order to be useful in the context of theorem proving, just providing the normal form is not sufficient. We need to establish a formal proof of the equivalence. In Isabelle, this means constructing a theorem  $t = t'$ , where  $t'$  is the normal form of  $t$ . We observe that in Algorithm 1 each equation can be recast in the following way: The input term is first transformed such that the outermost constitution is changed. Then, the whole term or subterms thereof are substituted by other functions—or recursively—, possibly multiple times. For instance, in the first equation (3.14) for nf-nf, the term  $g \text{'ap'} (f \text{'ap'} x)$  (where  $g, f, x$  should be understood as placeholders for concrete terms) is rearranged to  $\text{pure } \mathbf{B} \text{'ap'} g \text{'ap'} f \text{'ap'} x$ . The subterm  $\text{pure } \mathbf{B} \text{'ap'} g$  is passed to pure-nf and replaced by the result, say  $g'$ . nf-nf acts on  $g' \text{'ap'} f$ , yielding  $f'$ , such that the final term is  $f' \text{'ap'} x$ .

Table 3.1 shows all initial transformations. It is no coincidence that these are the well-known equivalences (3.3)–(3.6) and (3.8), which were used in the correctness proofs. Each transformation has been augmented with the corresponding HOL equation. The mapping from syntactic idiomatic terms to HOL terms is obvious; *pure* and  $\diamond$  are the concrete constants of the idiom under consideration. The variables standing for arbitrary opaque terms become new schematic variables, representing unknowns which may be instantiated. Rule B\_pure is easily proven by rewriting with B\_intro and merge. The other rules are the applicative laws and thus are available from the registration infrastructure. Applying a transformation to a term means instantiating the rule such that the left hand side is equal to that term. Isabelle provides a low-level reasoning framework for combining *conversions* [16], which we use here. A conversion is a function which takes a term  $t$  and returns a theorem

Function	Pattern	Substitution	Name
normalize	$\text{term } x$	$\simeq \text{pure}(\lambda x. x) \text{'ap' term } x$	I_intro
	$?x$	$= \text{pure}(\lambda x. x) \diamond ?x$	
nf-nf	$g \text{'ap' } (f \text{'ap' } x)$	$\simeq \text{pure } \mathbf{B} \text{'ap' } g \text{'ap' } f \text{'ap' } x$	B_intro
	$?g \diamond (?f \diamond ?x)$	$= \text{pure}(\lambda g f x. g(fx)) \diamond ?g \diamond ?f \diamond ?x$	
pure-nf	$\text{pure } g \text{'ap' } (f \text{'ap' } x)$	$\simeq \text{pure}(\mathbf{B} g) \text{'ap' } f \text{'ap' } x$	B_pure
	$\text{pure } ?g \diamond (?f \diamond ?x)$	$= \text{pure}(\lambda f x. ?g(fx)) \diamond ?f \diamond ?x$	
pure-nf	$\text{pure } f \text{'ap' } \text{pure } x$	$\simeq \text{pure}(f x)$	merge
	$\text{pure } ?f \diamond \text{pure } ?x$	$= \text{pure}(?f ?x)$	
nf-pure	$f \text{'ap' } \text{pure } x$	$\simeq \text{pure}((\lambda x. \lambda f. f x) x) \text{'ap' } f$	swap
	$?f \diamond \text{pure } ?x$	$= \text{pure}(\lambda f. f ?x) \diamond ?f$	

Table 3.1: Fixed transformations of Algorithm 1, with corresponding rewrite rules. Identity cases are omitted.

$t = u$  for some  $u$ .<sup>5</sup> The ML function `Conv.rewr_conv` turns a proven equation into such a conversion function. When the resulting conversion is applied, it attempts to instantiate the schematic variables in the equation. Note that conversions can fail; this may happen here if there is no match. Basic conversion combinators are the `then_conv` operator, which chains two conversions sequentially (and fails if any of these does), and the `else_conv` operator, which attempts to apply the first conversion, but uses the second if the first fails. Because rewrite conversions act like pattern matching guards, we combine them with `else_conv` to recreate the case switching of the algorithm. Combinators like `Conv.arg1_conv` facilitate the rewriting of subterms—this one takes a conversion and applies it to the left operand of a binary operator. With these tools at hand, we can construct the normal form conversion. The recursive parts can be expressed as recursive auxiliary functions. However, we lose some generality by using `Conv.arg1_conv` to access the left operand of  $\diamond$ , because it requires that  $\diamond$  is not a beta-redex. This could be solved by creating a specialized combinator, which does pattern matching instead of simple term deconstruction.

Figure 3.5 shows the ML code. It is parameterized by the applicative functor `af`, which contains all the necessary rules. In the helper function `normalize`, the different cases are selected by predicates like `can (dest_comb ctxt af) t`, which is true only if term  $t$  fits the pattern `_  $\diamond_{\text{af}}$  _`. We do this here because it is the only recursive conversion which is not guarded by a rewrite rule before recurring, so we want to protect against rampant rewriting. Finally, `rename_rewr_conv` and `rename_rr_conv` (not shown) adjust the names of bound variables in the argument rule to the term to convert. While these names are only hints in Isabelle and obviously subject to alpha conversion, they influence the display of the proof state. To elaborate, consider a HOL term  $p \diamond (q \diamond r)$ . Without the adjustment, the normal form would be  $\text{pure}(\lambda x x_a x_b. x(x_a x_b)) \diamond p \diamond q \diamond r$ . The name component  $x$  stems from the lambda abstraction in rule `B_intro`. If the term is part of an equation, the variables of the reduced base equation will also be called  $x$ ,  $x_a$ , and  $x_b$ . This creates unnecessary confusion, and to help the user, we try to preserve the variable names of the input term.

Figure 3.5: ML implementation of normalization.

## 4 Lifting with Combinators

### 4.1 Motivation

The normalization approach to solving lifted equations works only if the opaque terms on both sides coincide. This is not true for all equations of interest. Let's revisit the set version of addition of natural numbers,  $\oplus$  from Example 1. This operator is also commutative, so it should be possible to prove

$$X \oplus Y = Y \oplus X.$$

After unfolding and normalization, we get

$$\text{pure}(\lambda xy. x + y) \diamond X \diamond Y = \text{pure}(\lambda yx. y + x) \diamond Y \diamond X. \quad (4.1)$$

Clearly, this can't be solved with a standard congruence rule, because we would have to prove that  $X$  is equal to  $Y$ . Since we are concerned with transferring properties from a base domain, we don't want to assume anything about those opaque subterms.

Hinze showed that such equations can be solved if certain *combinators* can be lifted. Informally, combinators are functions which rearrange their arguments in a specific manner. We have already used two combinators, **I** and **B**. Lifting their defining equations (see Table 4.1) gives us the identity and composition laws, respectively. If the lifted combinator performs the same rearrangement with arbitrary functorial values, one can translate that particular term structure between the two levels. In this case, we simply say that the combinator *exists*. To continue with (4.1), we could attempt to change the order of  $Y$  and  $X$  on the right-hand side. Note that these appear as arguments to a pure function. The **C** combinator, also known as 'flip' in functional programming, does what we want:  $\mathbf{C}fxy = fyx$ . The lifted equation is

$$\text{pure } \mathbf{C} \diamond f \diamond x \diamond y = f \diamond y \diamond x, \quad (4.2)$$

and it is indeed true for set idiom! From this we get

$$\text{pure}(+) \diamond X \diamond Y = \text{pure}(\mathbf{C}(+)) \diamond X \diamond Y. \quad (4.3)$$

The right-hand side is no longer the normal form of  $Y \oplus X$ , but still a canonical form (which is why we distinguish these two). But now the argument lists on both sides coincide. We reduce to

$$\lambda xy. x + y = \lambda xy. y + x,$$

which is extensionally equivalent to the base equation  $x + y = y + x$ . The availability of equation (4.2) is a rather powerful condition, because it will allow us to permute opaque terms freely. If permutations exist such that both sides of an equation in canonical form align regarding their opaque terms, reduction by congruence is possible again. This will again lead to the expected base equation. However, the combinator **C** does not exist for all applicative functors. For example, the order of values in a state monad may be significant.

Combinators appeared originally in the context of logic [5]. They were studied because it is possible to write logical formulas without variables, using only applications of suitable

Symbol	Reduction
<b>B</b>	$\mathbf{B}xyz = x(yz)$

<b>W</b>	$\mathbf{W}xy = xyy$
<b>S</b>	$\mathbf{S}xyz = xz(yz)$

Table 4.1: Useful combinators.

combinators. Table 4.1 lists all combinators which are used throughout this text, together with their defining equations. There are certain sets of combinators which are sufficient to express all lambda terms,  $\{\mathbf{S}, \mathbf{K}\}$  being one of them. With other sets, only a part of terms is representable. Hinze’s Lifting Lemma shows that all terms and thus all equations can be lifted while preserving the variable structure if  $\mathbf{S}$  and  $\mathbf{K}$  exist. He also notes that other combinator set are useful, because there are idioms where more than  $\{\mathbf{B}, \mathbf{I}\}$ , but not all combinators exist. Generally speaking, additional combinators enlarge the set of equations which can be lifted.

The original proof of the Lifting Lemma [10, pp. 11–14] uses induction on the structure of idiomatic terms; it is not entirely obvious how it can be generalized to other combinator sets, as it depends on the availability of  $\mathbf{K}$  to lift tuple projections. In this section we present an implementation of this generalized lifting, whose underlying concept works with arbitrary combinators. However, it depends on an abstraction algorithm and the structure of representable terms, which are difficult to derive automatically. Therefore, we will restrict ourselves to certain sets (“bases”) with fixed algorithms, while understanding that the scope can be extended if needed.

## 4.2 Generic Lifting

We start with the relationship of combinators and lambda terms. The equations in Table 4.1 can be expressed as abstractions  $\mathbf{I} = \lambda x. x$  etc. If we substitute occurrences of combinators in a term (indicated by  $=_\delta$ ), new abstractions are introduced, which may be beta-reduced afterwards:

$$\mathbf{WB} =_\delta (\lambda fx. fxx)(\lambda gfx. g(fx)) =_\beta \lambda xy. x(xy).$$

The question arises when and how this process can be reversed, meaning that all abstractions are replaced by suitable combinators. In Curry et. al. [5, Section 6A], terms with variables, but no abstractions are considered. A syntactical operation is defined, denoted  $[x]t$ , where  $t$  is such a term and  $x$  is a variable. The desired property is that  $x$  does not occur in  $[x]t$ , and  $([x]t)x =_\delta t$ . Due to its notation, the operation is known as *bracket abstraction*. There is an obvious correspondence with lambda abstractions  $\lambda x. t$ . Bracket abstraction however stands for a concrete applicative term, whereas a lambda is an object of the syntax itself. Replacing lambdas  $\lambda x. t$  by brackets  $[x]t$  performs the shift to a combinator representation. Curry et. al. give several possible definitions for bracket abstraction. They note that these follow a scheme they refer to as an algorithm—a sequence of rules, where each rule is a partial definition. The rules may invoke abstraction recursively. In particular, the following rules are used:

$$\begin{aligned}
[x]x &= \mathbf{I}, & (i) \\
[x]t &= \mathbf{K}t & \text{if } x \text{ not free in } t, & (k) \\
[x]tx &= t & \text{if } x \text{ not free in } t, & (\eta) \\
[x]st &= \mathbf{B}s([x]t) & \text{if } x \text{ not free in } s, & (b) \\
[x]st &= \mathbf{C}([x]s)t & \text{if } x \text{ not free in } t, & (c) \\
[x]st &= \mathbf{S}([x]s)([x]t). & (s)
\end{aligned}$$

The algorithm which consists of rules (i), (k) and (s), in that order, is written succinctly as (iks). The algorithm attempts to use the rules in their left-to-right order, applying the first one whose restrictions are satisfied by the term at hand. Each abstraction algorithm  $A$  introduces a certain set of basic combinators, which we refer to as  $C(A)$ . It is sound only if certain postulates about those combinators, which are again the equations in Table 4.1, are assumed.

**Example 5.** Using the (iks) algorithm, one gets

$$[x]xxy \stackrel{(s)}{=} \mathbf{S}([x]xx)([x]y) \stackrel{(s),(k)}{=} \mathbf{S}(\mathbf{S}([x]x)([x]x))(\mathbf{K}y) \stackrel{(i)}{=} \mathbf{S}(\mathbf{SII})(\mathbf{K}y).$$

Attempting to use the (ik $\eta$ bc) algorithm with the same abstraction quickly comes to a stop:

$$[x]xxy \stackrel{(c)}{=} \mathbf{C}([x]xx)y,$$

which is undefined. ▲

As we can see, not all algorithms are total. Therefore, there is a trade-off between the combinators required and the terms for which abstraction is possible. Bunder [3] presents an analysis of the situation for certain algorithms and combinator sets, based on rigorous definitions for term translation and definability. We will come back to this later, when we discuss how to order the variables in an idiomatic term such that abstraction is defined. For now, the concept of bracket abstraction with the example of rules (i)–(s) is sufficient.

Next, we attempt to transfer these concepts to idiomatic terms. On the one hand, this is quite intuitive since the latter are also formed by an application operator, and pure terms can be identified with constants. But we do not have “idiomatic abstractions”. Hinze actually defines these in terms of abstract combinators and an extensionality property of the idiom. For our purpose it is sufficient to work directly with bracket abstraction, and we assume that all combinators are lifted, i.e., expressible as a pure term. To clarify the following discussion, we adjust our  $\mathcal{I}$  formalism and replace opaque terms  $\text{term } x$  with variables.

**Definition 6.** The set of generic idiomatic terms  $\mathcal{I}'$  is defined by

$$\mathcal{I}' ::= \text{var } \mathcal{V} \mid \text{pure } \mathcal{T} \mid \mathcal{I}' \text{ 'ap' } \mathcal{I}'. \quad (4.4)$$

We reuse the congruence  $\simeq$  from Definition 2 for generic terms. The set of variables  $\text{var}(t)$  of  $t$  is defined as the set of all arguments to  $\text{var}$  occurring in  $t$ . The sequence of variables  $\overrightarrow{\text{var}}(t)$  is defined similarly to  $\text{opaq}$ . Unlifting (see Definition 5) is also transferred, but uses the variable  $x$  in subterms  $\text{var } x$  instead of inventing new ones. ▲

Using this definition, it is clear what the rules for idiomatic abstraction are:

$$\begin{aligned}
[x]'(\text{var } x) &= \text{pure } \mathbf{I}, & (i') \\
[x]'t &= \text{pure } \mathbf{K} \text{ 'ap' } t & \text{if } x \notin \text{var}(t), & (k') \\
[x]'(t \text{ 'ap' } \text{var } x) &= t & \text{if } x \notin \text{var}(t), & (\eta') \\
[x]'(s \text{ 'ap' } t) &= \text{pure } \mathbf{B} \text{ 'ap' } s \text{ 'ap' } [x]'t & \text{if } x \notin \text{var}(s), & (b') \\
[x]'(s \text{ 'ap' } t) &= \text{pure } \mathbf{C} \text{ 'ap' } [x]'s \text{ 'ap' } t & \text{if } x \notin \text{var}(t), & (c') \\
[x]'(s \text{ 'ap' } t) &= \text{pure } \mathbf{S} \text{ 'ap' } [x]'s \text{ 'ap' } [x]'t. & (s')
\end{aligned}$$

In general, the algorithm  $A'$  on idiomatic terms is obtained from algorithm  $A$  on regular terms by lifting its rules in this fashion, preserving order.

The interchange law allows us to move a variable out of the left subterm of an application, given that the right subterm is pure. This is not captured by rules  $(b')$  and  $(i')$ , which are the only ones from above which are valid in all idioms. We define a combinator  $\mathbf{T}xy = yx$  and the rules

$$\begin{aligned}
[x]st &= \mathbf{T}t([x]s) & \text{if } t \text{ contains no variables,} & (t) \\
[x]'(s \text{ 'ap' } t) &= \text{pure } \mathbf{T} \text{ 'ap' } t \text{ 'ap' } [x]'s & \text{if } \text{var}(t) = \emptyset. & (t')
\end{aligned}$$

Soundness of rule  $(t')$  can be shown to be equivalent to the interchange law. It is important to understand that  $\mathbf{T}$  does not have to exist in the idiom; these rules do not fit exactly in the pattern of the other rules. The  $\mathbf{T}$  combinator is also necessary to formulate the most generic rule for the  $\mathbf{W}$  combinator. Without the interchange law, it could only be used for terms  $t \text{ 'ap' } \text{var } x \text{ 'ap' } \text{var } x$ , i.e. those where the same variable is applied twice in direct succession. In an idiom, there may be arbitrary pure terms inbetween the variables. We use the  $(w)$  rule when the variable occurs in both operands of an application, just like the  $(s)$  rule.

$$[x]st = \mathbf{W}(\mathbf{B}(\mathbf{T}[x]t)(\mathbf{B}\mathbf{B}[x]s)) \quad \text{if } [x]t \text{ contains no variables.} \quad (w)$$

$(w')$  is derived similarly to the other rules.

As with ordinary terms, we demand a soundness property for idiomatic bracket abstraction, namely that  $[x]'t' \text{ 'ap' } \text{var } x \simeq_C t'$  holds true. The definitions for the additional combinators  $C$  get lifted to  $\text{pure } \mathbf{I} \text{ 'ap' } x \simeq_C x$  and so on, consistently extending our congruence relation  $\simeq$  to  $\simeq_C$ .

**Lemma 7.** *Let  $t' \in \mathcal{I}'$  be a generic idiomatic term, and  $x \in \mathcal{V}$  a variable. For an abstraction algorithm  $A'$  consisting of a subset of rules  $(i')$ – $(t')$ , we have  $\downarrow [x]'t' = [x] \downarrow t'$  and  $[x]'t' \text{ 'ap' } \text{var } x \simeq_{C(A')} t'$ , assuming that  $[x]'t'$  is defined. Also, bracket abstraction does not add variables:  $\text{var}([x]'t') \subseteq \text{var}(t')$ .*

*Proof.* This statement uses that fact that the rules in  $A'$  are very similar to those of  $A$ . In particular, rule  $(r')$  is applied first when evaluating  $[x]'t'$  iff rule  $(r)$  is applied first to  $[x] \downarrow t'$ . The remainder of the proof is a simple induction. We show the case involving rule  $(c')$  as an example, the other cases are similar. Thus  $t = s \text{ 'ap' } u$  with  $x \notin \text{var}(u)$ . The induction hypothesis is

$$\downarrow [x]'s = [x] \downarrow s \quad \text{and} \quad [x]'s \text{ 'ap' } \text{var } x \simeq_{C(A')} s \quad \text{and} \quad \text{var}([x]'s) \subseteq \text{var}(s).$$

Then we have

$$\begin{aligned} \downarrow [x]'t &\stackrel{(c')}{=} \downarrow (\text{pure } \mathbf{C} \text{ 'ap' } [x]'s \text{ 'ap' } u) = \mathbf{C}(\downarrow [x]'s)(\downarrow u) \\ &\stackrel{(\text{IH})}{=} \mathbf{C}([x]\downarrow s)(\downarrow u) \stackrel{(c)}{=} [x](\downarrow s \downarrow u) = [x]\downarrow t \end{aligned}$$

and

$$\begin{aligned} [x]'t' \text{ 'ap' } \text{var } x &= \text{pure } \mathbf{C} \text{ 'ap' } [x]'s \text{ 'ap' } u \text{ 'ap' } \text{var } x \simeq_{C(A')} [x]'s \text{ 'ap' } \text{var } x \text{ 'ap' } u \\ &\stackrel{(\text{IH})}{\simeq_{C(A')}} s \text{ 'ap' } u = t. \end{aligned}$$

□

Now we can state the key observation: The successful abstraction of all variables in an idiomatic term leaves a single pure term, per the homomorphism law. Moreover, that term is equivalent to the result of applying the same abstraction algorithm to the “unlifted term”. In principle, this works with arbitrary rules, as long as the conclusions of Lemma 7 hold true.

**Theorem 2.** *In the following, bracket abstraction uses algorithms  $A$  and  $A'$  with a subset of the rules (i)–(t) and (i')–(t'), respectively. Let  $t' \in \mathcal{T}'$  be a generic idiomatic term, and  $x_1, \dots, x_n$  a permutation of the variables  $\text{var}(t')$ , or a superset thereof. If  $f = [x_1] \cdots [x_n] \downarrow t'$  is defined for  $A$ , then*

- a)  $[x_1]' \cdots [x_n]'t'$  consists only of applications of pure terms, and
- b) the unique canonical form of  $[x_1]' \cdots [x_n]'t'$  is  $\text{pure } f$ ;
- c)  $\text{pure } f \text{ 'ap' } \text{var } x_1 \text{ 'ap' } \cdots \text{ 'ap' } \text{var } x_n$  is a canonical form of  $t'$ ;
- d) replacing all combinators from  $C(A)$  in  $f$  with their definitions yields  $f' =_{\beta\eta} \lambda x_1 \cdots x_n. \downarrow t'$ .

*Proof.* a) is due to  $\downarrow ([x_1]' \cdots [x_n]'t') = f$  (induction and Lemma 7).

- b) It is not difficult to see that a pure-only term  $p$  has a unique canonical form, which is equal to  $\text{pure } \downarrow p$ .
- c) We have  $\text{pure } f \text{ 'ap' } \text{var } x_1 \text{ 'ap' } \cdots \text{ 'ap' } \text{var } x_n \simeq_{C(A)} t'$  by induction, making repeated use of Lemma 7.
- d) We show  $[x_1] \cdots [x_n] \downarrow t' =_{\delta\beta} \lambda x_1 \cdots x_n. \downarrow t'$ . Note that  $([x_i]p)x_i =_{\delta\beta} p$  for all terms  $p$ , and hence  $[x_i]p =_{\eta} \lambda x_i. ([x_i]p)x_i =_{\delta\beta} \lambda x_i. p$ .

□

Remember that we are interested in equations, which obviously consist of two idiomatic terms. We get to the base equation only if the same variable sequence is used for both terms, and the assumptions of Theorem 2 are satisfied. To complete the *generic lifting* approach, we need a procedure for determining the abstraction order. Since this procedure has to depend on the abstraction algorithm, we fix the combinator bases first. Hinze focuses on **SK** = **BCKW** and **BICS** = **BICW**, noting that **BIC** is also relevant. The set  $\{\mathbf{B}, \mathbf{I}, \mathbf{C}, \mathbf{K}, \mathbf{W}\}$  and its subsets seem to be a good starting point to cover relevant cases. The additional combinators play an intuitive role: **C** reorders variables, **W** duplicates them, and **K** permits abstraction over additional variables. Table 4.2 lists all distinct subsets containing **B** and **I**,

Base	Abstraction	Example idioms
<b>BI</b>	$(ibt)$	state, list
<b>BIC</b>	$(ibtc)$	set
<b>BIK</b>	$(kibt)$	
<b>BIW</b>	$(ibtw)$	sum type
<b>BCK</b>	$(kibtc)$	
<b>BKW</b>	$(kibtw)$	
<b>BICW</b>	$(ibtcs)$	maybe
<b>BCKW</b>	$(kibtcs)$	stream, $\alpha \rightarrow$

Table 4.2: Substructures of BCKW.

together with the abstraction algorithms we propose. We routinely ignore **T** when listing the combinators. This highlights the connection with combinatorial logic, where some of those bases have been studied.

The algorithms have been chosen in order to simplify the implementation, by activating the rules depending on the available combinators: If **K** exists, start with  $k$ . Then, for all bases, perform  $ibt$ . If **C** (or **W**) exists, add  $c$  (or  $w$ ), respectively. However, if both do, use rule  $s$  instead. Below follows a detailed description of how the variable sequence can be found in each base, and we justify the abstraction algorithms, meaning that the preconditions of Theorem 2 are satisfied. The function  $\text{abs}_C(s, t)$  will denote the chosen sequence for terms  $s, t$  in the context of base  $C$ . We write  $\langle \rangle$  for the empty sequence, and  $x \cdot \vec{y}$  means that element  $x$  is in front of the sequence  $\vec{y}$ .

## BI

This is the minimal base which is available for all idioms. We already know from Section 3.1 that there is only one canonical form with respect to  $\simeq$ . Therefore, there is exactly one permissible sequence:

$$\text{abs}_{\mathbf{BI}}(s, t) = \overrightarrow{\text{var}}(s) = \overrightarrow{\text{var}}(t).$$

Equations where the two sequences differ are rejected. If any other sequence could be used, we would get a different canonical form per Theorem 2, thus contradicting the previous result on normal forms. Focusing on a single abstraction step  $[x_i]t_i$ ,  $x_i$  must occur once in  $t_i$ , and it is the right-most variable. If  $t_i$  is an application, there are two cases:  $x_i$  occurs in the right subterm, and rule  $(b)$  is used successfully. Otherwise, there can be no variable in the right subterm, so  $(t)$  applies. This confirms that algorithm  $(ibt)$  is indeed acceptable for this base.

## BIC

Bunder shows in [3] that **BIC**-definable lambda terms are those where each bound variable occurs exactly once, irrespective of their order. His definition of a  $C$ -definable term  $t$  (with combinator base  $C$ ) implies that there exists an abstraction algorithm such that  $[x]s$  is defined if  $t = \lambda x. s$ . In particular,  $(i\eta bc)$  is a valid algorithm. From this it follows that we can choose the order in which we abstract, as long as the corresponding variable occurs exactly one. Note that our special **T** combinator is not considered there. But as it can be simulated by the more powerful **CI**, adding it to the combinator base does not change anything.

In this base, we can work with all equations where the variable sequence of one term can be reordered to the sequence of the second. The order used for the abstraction is irrel-

event, but it will be reflected in the quantifier order of the base equation. A simple choice is  $\text{abs}_{\mathbf{BIC}}(s, t) = \overrightarrow{\text{var}}(s)$ . However note that we do not use the  $(\eta)$  rule, but add the  $(t)$  rule.  $(\eta)$  could be considered as an optimization, since  $\lambda x. yx =_{\beta} \mathbf{B}y\mathbf{I}$ , so  $(b)$  and  $(i)$  suffice. Conversely,  $(t)$  is a special case of  $(c)$  with  $(i)$ , and adding it to the algorithm next to  $(c)$  just results in a slightly different combinator representation. We use this particular algorithm in order to simplify the implementation, such that as much code as possible can be shared between the bases.

## BCK and BICW

These cases were also analyzed by Bunder. For **BCK**, the definable terms are those where each bound variable occurs at most once, again ignoring the order. In terms of bracket abstraction,  $[x]y$  is then also defined if  $x$  is not free in  $y$ . This allows us to extend the sequence with other variables. We make use of this to deal with variables which only occur on one side of an equation—it does not hurt to abstract over those, too. Hence,  $\text{abs}_{\mathbf{BCK}}(s, t)$  can be any arrangement of the set  $\text{var}(s) \cup \text{var}(t)$ . The implementation uses a total order on the set of variables. On the contrary, the definable terms of **BICW** have at least one occurrence of each bound variable;  $[x]y$  can therefore be used if  $x$  occurs multiple times in  $y$ , and  $x$  will not be free in  $[x]y$ . Comparing this with **BIC**, we loosen the restriction that variables must not be repeated.  $\text{abs}_{\mathbf{BICW}}(s, t)$  must be an arrangement of  $\text{var}(s) = \text{var}(t)$ . We can compute this by sorting the sequences again, and then trimming duplicates which now are next to each other.

Bunder proposes the  $(i\eta kbc)$  algorithm for **BCK**, and  $(i\eta bcs)$  for **BICW**; our rules are  $(kibtc)$  and  $(ibtcs)$ , respectively. The comments on  $(\eta)$  and  $(t)$  from above apply here as well. The only other difference is the position of  $(k)$  in the list. But  $(k)$  on one side and  $(i)$  and  $(\eta)$  on the other work with disjoint sets of terms, so this is not an issue.

## BCKW

This base, which is logically equivalent to **SK**, has some useful properties:  $[x]y$  can always be defined, making it possible to use any abstraction sequence, and in turn handle all equations. In conjunction with Theorem 2, we want to abstract all free variables, though. Therefore we determine the sequence as with **BCK**, but the term restriction is rescinded. As for the abstraction algorithm, we use a variation of  $(ik\eta bcs)$  from [5].

## BIK, BIW and BKW

These bases do not appear to be significantly covered in the literature. Since there is at least one useful example of an idiom with **BIW** combinators, we still shall implement and discuss them. By adding the **K** combinator to **BI**, additional variables may be abstracted, but the other restrictions (order, single occurrence) remain. Accordingly, we demand that  $\text{abs}_{\mathbf{BIK}}(s, t)$  has  $\overrightarrow{\text{var}}(s)$  and  $\overrightarrow{\text{var}}(t)$  as subsequences. For definiteness, we can limit it to the shortest sequence where variables only in  $s$  appear before those only in  $t$ , whenever there is an ambiguity:  $\text{abs}_{\mathbf{BIK}}(s, t) = \text{abs}'_{\mathbf{BIK}}(\overrightarrow{\text{var}}(s), \overrightarrow{\text{var}}(t))$ ,

$$\text{abs}'_{\mathbf{BIK}}(a, b) = \begin{cases} x \cdot \text{abs}'_{\mathbf{BIK}}(a', b') & \text{if } a = x \cdot a', b = x \cdot b'; \\ x \cdot \text{abs}'_{\mathbf{BIK}}(a', b) & \text{if } a = x \cdot a', \\ x \cdot \text{abs}'_{\mathbf{BIK}}(a, b') & \text{if } b = x \cdot b', \\ \langle \rangle & \text{if } a = b = \langle \rangle. \end{cases}$$

Trying rule  $(k)$  in the beginning of the abstraction algorithm obviously takes care of unused variables.

For the other bases, we simply take the abstraction algorithms as granted. Based on that we analyze the set of defined bracket abstractions. Since **W** duplicates variables, one might conjecture that a single variable may now occur repeatedly. No other variable may be interspersed, because none of the available combinators reorder their arguments. The following lemma proves that this intuition is correct. In order to express it on the level of lambda terms, we overload  $\vec{\text{var}}(x)$  in the obvious way. We use the notation  $x^n$  with sequence  $x$  to stand for  $n$  concatenated copies of  $x$ .

**Lemma 8.** *Let  $x \in \mathcal{V}$  and  $t \in \mathcal{T}$ . With algorithm  $(ibtw)$ ,  $[x]t$  is defined iff there is a natural number  $n \geq 1$  and a variable sequence  $v$  such that  $\vec{\text{var}}(t) = v @ \langle x \rangle^n$ , where  $x$  does not appear in  $v$ . The same statement holds true for algorithm  $(kibtw)$ , except that  $n$  may be zero.*

*Proof.* The first part of the proof is concerned with the direction where  $[x]t$  is assumed to be defined. We perform induction over the steps of the abstraction algorithm. In the evaluation of  $[x]s$  for a subterm  $s$  of  $t$ , there are the following cases: If  $(k)$  is used, then  $x$  must not be free in  $s$ , thus  $n = 0$  and  $v = \vec{\text{var}}(s)$ . For  $(i)$ , we have  $n = 1$  and  $v = \langle \rangle$ . For  $(b)$ , there must be terms  $u$  and  $w$  with  $s = uw$ , and  $x$  is not free in  $u$ . From the induction hypothesis we get adequate  $n'$  and  $v'$  for  $[x]w$ . Then  $n'$  and  $\vec{\text{var}}(u) @ v'$  satisfy the conditions for  $[x]s$ . Rules  $(t)$  and  $(w)$  are analogous: For  $(t)$ , the side condition implies that  $\vec{\text{var}}(w) = \langle \rangle$ ; for  $(w)$  we have  $\vec{\text{var}}(w) = \langle x \rangle^k$  for some  $k \geq 1$ , thus  $\vec{\text{var}}(u) @ \vec{\text{var}}(w) = v' @ \langle x \rangle^{n'+k}$ , where  $n'$  and  $v'$  are from  $[x]u$ .

Now we show the other direction. Assume that suitable  $n$  and  $v$  exist. If  $n = 0$ , rule  $(k)$  is used, because  $x$  cannot be free in  $t$ . Otherwise we assume  $n \geq 1$  during an induction on the structure of  $t$ . If  $t$  is a variable, it must be  $x$ , so rule  $(i)$  applies. If it is an application  $s = uw$  instead, there are three cases:  $x \notin \text{var}(u)$ , hence  $v = \vec{\text{var}}(u) @ v'$  for some  $v'$ , and  $[x]w$  is defined by the induction hypothesis so we can use rule  $(b)$ . If  $\text{var}(w) = \emptyset$ ,  $[x]u$  is defined and rule  $(t)$  applies. Otherwise,  $\vec{\text{var}}(w) = \langle x \rangle^k$  with  $k \leq n$  must hold, so  $(w)$  can be used.  $\square$

It follows that the abstraction sequences for **BIW** and **BKW** should be chosen like those of **BI** and **BIK**, respectively; but for each variable, a single span of repetitions in  $\vec{\text{var}}(s)$  and  $\vec{\text{var}}(t)$  is allowed and treated like a single instance.

### 4.3 Implementation

The implementation of generic unlifting essentially has to compute bracket abstractions, i.e., recursively select the correct rule for a term. Similar to what we did with the normal form conversion, the goal is to prove a theorem representing

$$t \simeq ([x_1]' \cdots [x_n]'t) \text{'ap'} x_1 \text{'ap'} \cdots \text{'ap'} x_n.$$

However, we also add a heuristic that tries to determine how variables have been instantiated in the supplied equation. First, arbitrary opaque terms take the place of variables. We can work directly with these, but it becomes less clear which come from the same variables, meaning that they should be abstracted simultaneously. Consider a base equation with two, universally quantified variables  $x$  and  $y$ . If the lifted version can be proven, it will also have two variables. Now, the user might want to prove a proposition which is equivalent to the lifted equation, except that both variables have been replaced by the (same) term  $z$ . This

modified statement is obviously true, so we might expect that the lifting tool can handle it. Remember that we prohibited multiple occurrences in certain bases, e.g. **BI**, when we defined bracket abstraction. What would happen if we normalize the equation? Normalization treats each instance of an opaque subterm separately, thus we will get something of the form  $\text{pure } f \diamond z \diamond z = \text{pure } g \diamond z \diamond z$ . By magic, the functions  $f$  and  $g$  have been equipped with two arguments! In the base **BI**, generic unlifting is no more powerful than normal form conversion, but we expect it not to be weaker either. We solve the problem by handling each opaque subterm as if it were a different variable. For other bases, we need to be more clever, or we would lose the advantage that generic unlifting was supposed to give us. For example, idempotency of an operator  $\circ$ ,  $x \circ x = x$ , can be lifted if **W** exists; when proving a lifted instance like  $f(x) \hat{\circ} f(x) = f(x)$ , the two copies of  $f(x)$  on the left-hand side must be identified. Therefore, the base of the idiom influences the assignment of “virtual” variables to opaque terms. In general, it is best if we identify as many terms as possible: The resulting base equation is certainly provable if it were so without grouping some pair of variables. However, we will see that the situation can sometimes be ambiguous.

```

1 datatype apterm =
2   Pure of term | Var of int * term | Ap of apterm * apterm;

```

Figure 4.1: The datatype to keep track of idiomatic terms.

We use a ML datatype to make the term structure explicit. `apterm` (see Figure 4.1) has a similar structure as  $\mathcal{I}$ . Opaque terms `Var` are tagged with an integer, which is unique for each position in an equation. Sets of these positions play the role of variables in the previous section. The function `eliminate` takes an `apterm`  $t$  and such a set  $x$ , computing the pair  $([x]'t, \phi)$ , where  $\phi$  is the theorem  $t \simeq [x]'t \text{ 'ap' } x$ . One important building block for this function is `rewr_subst_ap`, whose code is shown in Figure 4.2. It combines three rewrite rules. Two of them, say  $x = x'$  and  $y = y'$ , get merged to a congruence rule of the idiomatic application operator,  $x \diamond y = x' \diamond y'$ , by the standard `Drule.binop_cong_rule`. However, the application operator’s types need to be instantiated before. The resulting equation is then chained with the third rule. Similar to our use of conversion combinators in Section 3.2, we employ `rewr_subst_ap` to handle the recursive nature of most abstraction rules. As an example refer to Figure 4.3, which shows rule  $(b')$ . It takes two pairs of an idiomatic term and a theorem as arguments, the results of abstracting the two subterms of an application. The main transformation is again provided by `B_intro` from Table 3.1. We must also update the `apterm` structure. New combinator terms are introduced, which need proper type instantiation. Because these combinators are part of the equation we have computed, it seems to be the easiest method to extract the terms from that equation. The integer supplied to `extract_comb` indicates how deeply nested to the left the combinator is.

The function `consolidate` determines the common abstraction sequence for two idiomatic terms. It begins with creating a left-to-right list of the variables for each term. Then an additional tag is added such that two list elements have the same tag iff we consider the instantiated terms equal. In the current implementation, the equality predicate is alpha convertibility. The next steps depend on the combinator base:

- a) If **C** exists, each list is sorted according to the tag. This groups equal terms together.
- b) If **W** exists, adjacent copies of the same term (again as indicated by the tag) are merged

```

1 fun rewr_subst_ap ctxt af rewr thm1 thm2 =
2   let
3     val funT = thm1 |> Thm.lhs_of |> Thm.typ_of_cterm;
4     val ap_inst = Thm.ctrm_of ctxt (ap ctxt af funT);
5     val rule1 = Drule.binop_cong_rule ap_inst thm1 thm2;
6     val rule2 = Conv.rewr_conv rewr (Thm.rhs_of rule1);
7   in Thm.transitive rule1 rule2 end;

```

Figure 4.2: The `rewr_subst_ap` function.

```

1 fun extract_comb n thm = Pure (thm |> Thm.rhs_of |>
2   funpow n Thm.dest_arg1 |> Thm.term_of);
3 fun comb2_step def (tt1, thm1) (tt2, thm2) =
4   let val thm = rewr_subst_ap def thm1 thm2;
5   in (Ap (Ap (extract_comb 3 thm, tt1), tt2), thm) end;
6 val B_step = comb2_step (#B_intro rules);

```

Figure 4.3: Implementation of rule  $(b')$ .

Figure 4.4: Example of the merge operation for **K** in `consolidate`. (1) Variable  $c$  can be aligned with the remainder of list  $r$ , which is not possible with  $f$  and list  $l$ . (2) Neither  $d$  nor the copy of  $a$  can be aligned, so we intersperse them. The previous occurrence of  $a$  is not considered, because the algorithm is greedy and works from left to right. (3) A single tail is preserved.

in each list. The positions of the involved variables are collected into a list. Otherwise, each position is put in an singleton list, so we have a uniform type after this step.

- c) If **K** exists, both lists are merged in a peculiar way: If the heads of them have the same tag, we merge their positions to obtain a single element and add it to the result, then proceeding with the tails. Otherwise, we try to align one head with the other list and vice versa. A head is aligned if its tag occurs in the list after some prefix. If alignment is possible in one direction, but not the other, the prefix and the aligned element become part of the result. Otherwise, the two heads are emitted one after the other. A potentially remaining single tail is kept as-is. Figure 4.4 displays an example.

If **K** does not exist, we check that both lists have the same length and contain the same sequence of tags, or an error condition is raised. Again, the position lists within both lists are zipped.

We should investigate whether this algorithm is consistent with the theoretical development in Section 4.2, and also with the criteria regarding variable instantiation.

- With **BI**, there is not much flexibility—we can only abstract over a single position at a time. Aborting due to a sequence mismatch is basically the single difference to normal form conversion. However, there we likely get an unprovable result, so this behavior is justified.
- **BIC**: As before; sorting produces a suitable sequence if one exists.
- **BIW**: We have shown that simultaneous abstraction is only possible for coherent spans of a variable. Merging all adjacent copies of a variable is the best we can hope for.
- **BICW**: Sorting puts equal terms next to each other, where they will be merged. Thus, all possible terms are identified, making this the most general solution. If the sanity check at the end fails, then the set of variables for both sides of the equation must differ, and the precondition for this base is violated.
- **BCKW** differs from the previous case in the last step. As expected, we now accept every pair of terms. It should not happen that we will get a duplicate variable tag, in other words, if a tag appears in both lists, there must be a single element in the output. This is easily shown by induction. Especially if alignment is used, the “skipped” prefix can only contain variables which do not occur in both terms, because the lists are sorted.
- **BCK**: The lack of **W** implies that all positions have to be abstracted individually. However, it is interesting to see what the **K** step does with respect to consolidating both sides of the equation. Again by induction we see that as many pairings as possible between the two sides of the equation are created. The difference to **BCKW** is that the same term may occur repeatedly in the lists. In case of different repetition counts, the algorithm is biased to the left. This is a potentially destructive choice, but the user can always resort to using new variables in the desired manner, and then do the instantiation in a second step.
- **BIK** and **BKW** are not perfectly solvable either. For example, consider the lists (tags only)  $\langle 1, 2 \rangle$  and  $\langle 2, 1 \rangle$ . If we try to consolidate, then  $\langle 1, 2, 1 \rangle$  or  $\langle 2, 1, 2 \rangle$  are the only possible sequences. It is not clear which is the correct one. The algorithm bails out and selects  $\langle 1, 2, 2, 1 \rangle$  (which is probably useless). Likewise, discretion on behalf of the user is required. One could try more sophisticated algorithms like minimizing the edit distance. Due to a lack of example idioms for these bases, we decided against this extra effort.

## 5 Usage Examples

### 5.1 User Interface

This section demonstrates the user interface of our package by revisiting Example 1. We assume that  $\oplus$  and  $\diamond$  for sets have been defined according to equations (1.5) and (1.4), and “set\_plus\_def” and “ap\_set\_def” refer to these equations. It is possible to prove the associative property with the standard facilities of Isabelle/HOL, of course. Figure 5.1 shows a canonical Isar proof. Its structure follows natural reasoning about sets: We prove set equality by showing mutual inclusion in both directions, each of which is proven by the corresponding implication. The operators in the term  $a \in X \oplus Y \oplus Z$  are unfolded to obtain nested set comprehensions. The fully automatic proof method *blast* is fortunately able to deduce the relation to elements of the individual sets  $X, Y, Z$ . Also note how the fact “add.assoc” is used in the middle—it states the base equation.

The proof scheme can be adjusted for other properties. It is, however, suitable only for the set idiom. Inductive datatypes would likely need induction (or case splits for non-recursive types), coinductive datatypes use coinduction, and so on.

Now we want to automate the full proof with our package. First, it needs to be informed about the set idiom. We provide a command to declare applicative functors:

```
applicative set (C) for
  pure:  $\lambda x. \{x\}$ 
  ap:  $\diamond_{set}$ 
unfolding ap_set_def by fast+

lemma set_plus_assoc:  $(X \oplus Y) \oplus Z = X \oplus (Y \oplus Z)$ 
proof
  show  $X \oplus Y \oplus Z \subseteq X \oplus (Y \oplus Z)$  proof
    fix  $a$  assume  $a \in X \oplus Y \oplus Z$ 
    then obtain  $x\ y\ z$ 
      where elems:  $x \in X\ y \in Y\ z \in Z$ 
      and sum:  $a = x + y + z$ 
      unfolding set_plus_def ap_set_def by blast
    from sum have  $a = x + (y + z)$  using add.assoc by simp
    with elems show  $a \in X \oplus (Y \oplus Z)$ 
      unfolding set_plus_def ap_set_def by blast
    qed
  next
    show  $X \oplus (Y \oplus Z) \subseteq X \oplus Y \oplus Z$  proof
      symmetric proof omitted ...
    qed
qed
```

Figure 5.1: A semi-manual proof of the associative property of addition, lifted to sets.

Its general syntax is

```
applicative name (combinator, ...)
for
  pure: puref
  ap:  $\diamond_f$ 
  proof
```

The idiom will be made available under the *name*. It can be used to refer to the idiom manually in proofs. The name is followed by an optional list of a subset of the symbols C, K, and W. These declare which combinators are lifted, as explained in Section 4. The set idiom only lifts the **C** combinator. The functions *pure* and  $\diamond$  imply the type scheme, see also Section 2.3. Finally, the idiom laws need to be proven. The system presents the user with corresponding goals, which are solved by the proof. For sets, the goals are

1.  $\bigwedge x. \{\lambda x. x\} \diamond x = x$
2.  $\bigwedge g f x. \{\lambda g f x. g(fx)\} \diamond g \diamond f \diamond x = g \diamond (f \diamond x)$
3.  $\bigwedge f x. \{f\} \diamond \{x\} = \{fx\}$
4.  $\bigwedge f x. f \diamond \{x\} = \{\lambda f. fx\} \diamond f$
5.  $\bigwedge f xy. \{\lambda f xy. fyx\} \diamond f \diamond x \diamond y = f \diamond y \diamond x$

In this example, the proof obligations are easily discharged by unfolding and the automatic *fast* prover. After the command has been issued, the functor can be used in subsequent commands. Its data is stored in the theory context and thus can be imported along other theory content. This allows the construction of a reusable idiom library.

Next, the definition of  $\oplus$  needs to be registered. Otherwise, the proof method is not able to interpret a term like  $X \oplus Y$  as a composite idiomatic expression. Lifted constants can be registered with the attribute *applicative\_unfold*, which can be applied to facts  $lhs = rhs$ , where *rhs* is an idiomatic expression. The equation must be suitable for rewriting.

Finally, we are able to compress the proof to a single invocation of the new proof method *applicative\_lifting*. The base equation is provided as a fact, and the Isar framework uses it automatically:

```
lemma set_plus_assoc:  $(X \oplus Y) \oplus Z = X \oplus (Y \oplus Z)$ 
using add.assoc by applicative_lifting
```

The proof method can also be used when the variables in the lifted equation have been instantiated with other terms. This situation may occur when the lifted property needs to be shown as a part of a larger proof, for example.

## 5.2 Lifted Algebra

Examples of operators with associated properties can be found in algebra. The HOL library contains a hierarchy of type classes which represent algebraic structures. Type classes [7] augment types with overloaded operators and related assumptions, and enable abstract reasoning based on these. In order to show that a type is an instance of such a class, the assumptions have to be proven. Conversely, we obtain these assumptions as theorems if a type (or type variable) is constrained to the class. Therefore, we can lift class instances to individual

functors. Note that this has to be done separately for each class, even if there is a subclass relationship. For example, assume that class  $B$  is a subclass of class  $A$ . If we have proven that a certain idiom preserves instances of  $B$ , we do not necessarily know that it preserves  $A$  as well (however, the lifted variant of a type of class  $B$  is certainly an instance of  $A$ , which is a different proposition).

We lift addition and multiplication to two similar datatypes, streams and infinite binary trees. Both can be modelled as codatatypes in Isabelle, using the revised datatype package [1]. Instead of using coinduction to construct the proofs manually, we employ our package. The following class instances are directly provable:

- semigroup, abelian semigroup,
- monoid, commutative monoid,
- commutative monoid with bounded subtraction (`comm_monoid_diff`),
- group,
- semiring,
- multiplicative zero.

(Other instances, for example for rings, follow trivially.) The instance proofs are usually not more complicated than e.g.

```
instance stream :: (monoid_add) monoid_add
by intro_classes (applicative_lifting, simp)+
```

The simplifier is used here to discharge the base property, which is provided by the class constraint on the base type. Note that the proof itself is not specific to streams after the lifting method has been applied. Thus, the instantiation is easily adapted for other types, once they are registered as an applicative functor.

As a counterexample, the class for semigroups with cancellation is outside the scope of our package: The laws

$$\bigwedge abc. a + b = a + c \implies b = c$$

$$\bigwedge abc. b + a = c + a \implies b = c$$

are not plain equations. For the reason outlined above, just lifting the group class (a subclass) is not sufficient to derive this instance.

## 6 Conclusion

### 6.1 Related Work

There already exist libraries for Isabelle/HOL which perform certain kinds of lifting. In this section, we want to highlight two of them and discuss how they compare to our solution. The first package [12] implements a “transfer principle” specifically designed for nonstandard analysis (NSA). It focuses on a fixed target type constructor,  $\alpha\ star$ . Certain instances of  $\alpha\ star$  constitute the nonstandard number types. For instance, the hypernatural numbers are elements of  $\text{nat}\ star$ . Arithmetic operators and their properties have to be lifted in order to develop their theory, which is automated by the transfer tactic. Its goal is indeed very similar to ours, but just focused on one application. Interestingly, the author of the NSA transfer package made use of the applicative structure of  $\alpha\ star$  to define lifted operators, as well as predicates. The latter is something the package presented in this report does not support. We will briefly discuss it as a potential extension in the next section.

The automated lifting of properties is not generic over idioms, though. This makes it possible to state all required rules directly as polymorphic HOL theorems. The tactic takes some lifted proposition, tries to find the base form by deleting certain constants (compare this to our unfolding approach), and then shows logical equivalence of the two by backchaining with suitable transfer rules. There is only little control by the ML implementation, as the process is mainly guided by resolution with rule patterns. Note that all parts of the input proposition go through the same process, including logical operators such as quantifiers and equality. This is a good place to mention that  $\alpha\ star$  is based on the function type  $\text{nat} \Rightarrow \alpha$ . Therefore, all combinators can be lifted; variables can be handled by resolution, because their order or duplication do not matter; all logical operators are preserved by lifting (the lifted type can be thought of as a collection of parameterized copies of the base formula).

We observe that the NSA transfer package is a lot more general than ours with respect to lifted propositions, but is restricted to one particular idiom. Many of the additional logical operators can only be lifted because of its special properties.

The other package collection we want to discuss provides quotient types. A quotient type is created from an existing type, the representation, and an equivalence relation on it; its elements are isomorphic to the equivalence classes. The *Lifting* and *Transfer* packages [13] constitute a modular infrastructure for transferring results from the representation level to the new type. *Transfer* finds and proves equivalences or implications between propositions according to an extensible set of transfer rules. These describe how two different functions (or type instances of the same function) are related, given relations of their arguments. *Transfer* is heavily driven by the type structure, following the principle of relational parametricity. The goal of *Lifting* is to automate the specification of constants lifted to quotient types. Because this kind of lifting preserves properties by construction, these should be carried over as well. Therefore, the package uses transfer to relate the new constant with its representation.

The relations used by transfer cannot express lifting to applicative functors. Values of the latter are usually more complex than those of the base type, instead of more abstract. We would need to find relations which are strong enough to lift arbitrary predicates. This is clearly not possible for functors with effects. To summarize, the actual lifting step of

our package is very simple, because it just considers pairs of extensionally equal functions; the whole automation is necessary to extract these functions from idiomatic expressions in the first place. Transfer, on the other hand, preserves the term structure, but relates each component of the term, and composes these relations according to the transfer rules.

## 6.2 Summary and Future Extensions

We have successfully implemented Hinze’s applicative lifting as a proof method for Isabelle/HOL. It can be instantiated for arbitrary idioms, making it a (hopefully) reusable tool. Since it supports several combinator sets, we take advantage of the individual properties of the idioms. The proof methods has been used to produce direct proofs of various algebraic laws for streams and infinite binary trees.

The choice of a shallow embedding led to a rather compact implementation, next to the registration infrastructure, which is necessary either way. The highly polymorphic situation demands constant care for type parameter instantiations, which is tedious. On the other hand, this is a problem for a deep embedding as well.

The current implementation is restricted to equations. As we have seen above, certain idioms can lift quite a lot more. A practical example are cancellation laws of a lifted binary operator, which have the structure  $\_ = \_ \implies \_ = \_$  (see also Section 5.2). We had to prove these manually for the stream and infinite tree theories. Again, variables make our live difficult: The lifted assumption does not necessarily imply the base assumption for *all* instances, and we cannot eliminate the implication to continue with the conclusion only. It is not obvious which additional conditions are necessary or sufficient to lift such properties. We have seen that the “power” of the various idioms differs with respect to combinators. Those which are homomorphic to the environment functor (streams, etc.) seem to be the most versatile. It might be interesting to survey possible categorizations and how they lead to further proof automation.
